Activatable Zymography Probes Enable In Situ Localization of Protease Dysregulation in Cancer

Ava P. Soleimany1,2,3, Jesse D. Kirkpatrick1,2, Susan Su1,4, Jaideep S. Dudani1,5, Qian Zhong1, Ahmet Bekdemir1,2, and Sangeeta N. Bhatia1,2,6,7,8,9,10,11

ABSTRACT

Recent years have seen the emergence of conditionally activated diagnostics and therapeutics that leverage protease- cleavable peptide linkers to enhance their specificity for cancer. However, due to a lack of methods to measure and localize protease activity directly within the tissue microenvironment, the design of protease- activated agents has been necessarily empirical, yielding suboptimal results when translated to patients. To address the need for spatially resolved protease activity profiling in cancer, we developed a new class of in situ probes that can be applied to fresh-frozen tissue sections in a manner analogous to immunofluorescence staining. These activatable zymography probes (AZP) detected dysregulated protease activity in human prostate cancer biopsy samples, enabling disease classification. AZPs were leveraged within a generalizable framework to design conditional cancer diagnostics and therapeutics and showcased in the Hi-Myc mouse model of prostate cancer, which models features of early pathogenesis. Multiplexed screening against barcoded substrates yielded a peptide, S16, that was robustly and specifically cleaved by tumor-associated metalloproteinases in the Hi-Myc model. In situ labeling with an AZP incorporating S16 revealed a potential role of metalloproteinase dysregulation in proliferative, premalignant Hi-Myc prostatic glands. Systemic administration of an in vivo imaging probe incorporating S16 perfectly classified diseased and healthy prostates, supporting the relevance of ex vivo activity assays to in vivo translation. We envision AZPs will enable new insights into the biology of protease dysregulation in cancer and accelerate the development of conditional diagnostics and therapeutics for multiple cancer types.

Significance: Visualization of protease activity within the native tissue context using AZPs provides new biological insights into protease dysregulation in cancer and guides the design of conditional diagnostics and therapeutics.

Introduction

Protease activity is dysregulated in cancer and contributes to all of its hallmarks, such as aberrant growth, neoangiogenesis, and immune evasion (1). For example, matrix metalloproteinases (MMP) are one of several classes of enzymes known to degrade the extracellular matrix, enabling tumor invasion and metastasis (2). As a result of this dysregulation, proteases have long been considered as a potential diagnostic and therapeutic target of cancer. The past decade has seen the emergence of new classes of conditional, or “activity-based,” diagnostics (3–10) and therapeutics (11–16), which are selectively activated in response to proteases dysregulated in cancer. Probes, for example, are a novel class of conditional therapeutics consisting of a tumor-targeting antibody masked via a protease-cleavable linker (11), which improves tumor specificity and reduces off-target toxicity. Likewise, activity-based diagnostics have demonstrated promise both preclinically and clinically, leveraging protease dysregulation in cancer to improve imaging specificity or intraoperative evaluation of tumor margins (4–6, 17–20).

To date, conditional diagnostics and therapeutics have incorporated peptide linkers that are identified via in vitro screens using recombinant proteases, which do not recapitulate the complex interplay of proteases and inhibitors in native tissue contexts, nor the substantial cross-cutting inherent to short peptide sequences (1, 5). As a result, the clinical utility of “conditional activation” has largely been limited to applications that do not require precise specificity for cancer (e.g., intraoperative imaging probes) or that incorporate additional layers to enhance specificity (e.g., probodies targeting tumor-associated antigens). The development and expansion of the principle of conditional activation is currently hindered by a dearth of methods to dissect protease activity in the native tissue context (1). Methods to identify peptide substrates that are maximally cleaved by tumor-associated proteases and minimally degraded in healthy tissues would provide a modular, broadly applicable means to address this engineering challenge. Multiplexed methods for substrate screening in biospecimens could yield candidate substrate linkers with high tumor specificity. Furthermore, the ability to localize these cleavage events in situ (i.e., in a tissue section) could enable finer dissection of cancer-associated protease biology, as the distribution of active proteases across the tumor invasive front, and yield new mechanistic insights that could in turn help validate select substrates for a given application. Finally, to accelerate translation, these methods must be compatible with...
Several methods have been developed with the aim of measuring protease activity in bulk biospecimens (21-24). Recent approaches leveraging synthetic substrates have used droplet-based microfluidics (25) or highly multiplexed peptide libraries (26, 27) to profile protease activity in patient-derived biospecimens. However, these assays do not provide insight on spatial localization of protease activity within the tissue. In situ zymography has long been the gold standard for visualizing protease activity in tissue sections (28), but this method is limited to visualizing the activity of proteases against natural cleavage sites in gelatin and therefore lacks the modularity to accommodate the chemical diversity necessary to identify disease-specific peptide substrates. Recent efforts to visualize the cleavage of synthetic peptides have relied on the expression of receptors (11, 29) or integrins (8) for probe binding, limiting their modularity and generalizability. Activity-based probes (ABP) leverage reactive warheads to covalently bind to protease active sites, enabling detection of active proteases in vivo and ex vivo (5, 30). However, because ABPs detect protease activity via covalent binding rather than substrate cleavage, they are less compatible with proteases of certain catalytic classes and cannot be used as a pure readout of tumor-specific peptide cleavage (5).

We therefore developed modular, cleavage-based activatable zymography probes (AZP) to localize substrate-specific proteolyis in tissue sections and applied this tool to prostate cancer models and samples. When applied to a human tumor microarray, AZPs achieved robust classification of prostate cancer biopsy samples, supporting their applicability to human cancer. We then leveraged a clinically relevant motif to monitor the activity of AZPs to probe the biology of cancer-associated protease dysregulation and to thus inform the bottom-up design of a conditionally activatable agent. We performed a multiplexed screen and discovered a single peptide that was specifically cleaved by disease-associated metalloproteinases in a genetically engineered mouse model (GEMM) of prostate cancer. This substrate was then translated into an AZP, which, when applied to tissue sections, revealed metalloprotease-dependent peptide cleavage in proliferative, premalignant prostatic glands. Finally, we translated this substrate into a protease-activated diagnostic that selectively accumulated in diseased mouse prostates in vivo. These results suggest that substrates validated through ex vivo activity profiling can be directly translated into in vivo conditionally activated diagnostics or therapeutics, accelerating the design, build, and test cycle. We envision that AZPs will facilitate design of protease-activatable diagnostics and therapeutics and advance understanding of protease dysregulation in human cancer.

Materials and Methods

Peptide synthesis

All peptides were synthesized by CPC Scientific (Sunnyvale, CA) and reconstituted in dimethylformamide (DMF) unless otherwise specified. Sequences are provided in Supplementary Table S1.

Buffer solutions

All buffer recipes are provided in Supplementary Table S2.

Hi-Myc prostate cancer model

All animal studies were approved by the Massachusetts Institute of Technology (MIT, Cambridge, MA) committee on animal care (protocol 0420–023–23). Reporting complied with Animal Research: Reporting In Vivo Experiments (ARRIVE) guidelines. Hi-Myc mice (FVB-Tg(ARR2/Pbsn-MYC)/Key/Nci) were obtained from Jackson Labs. The Hi-Myc model was generated as described previously (31). Briefly, c-Myc is expressed via a prostate-specific transgenic construct, ARR/probasin–Myc, which contains androgen response elements that drive androgen-dependent expression of c-Myc within the murine prostate. Age-matched healthy male FVB/NJ mice (Jackson Labs) were used as controls in all experiments.

Mouse dissections and tissue isolation

For prostate tissue, urogenital organs from Hi-Myc mice and age-matched healthy male FVB/NJ mice were isolated, and prostates were microdissected. Adipose tissue surrounding the prostates was removed using forceps, and the entirety of the mouse prostate was separated from the urethra. For preparation for tissue homogenization, prostates were flash-frozen in liquid nitrogen and stored at ~80 °C until use. For preparation for cryosectioning, prostates were immediately embedded in optimal-cutting-temperature (OCT) compound (Sakura), and frozen using isopentane chilled with dry ice. Colons were harvested from healthy C57BL/6J mice (Jackson Labs), rinsed with PBS to remove feces, filled with undiluted OCT using a blunt 20-gauge needle, embedded in OCT, and frozen using isopentane chilled with dry ice.

Synthesis of peptide-functionalized magnetic beads

Amine-functionalized magnetic beads (Dynabeads M-270 Amine, Invitrogen) were washed and resuspended in PBS prior to coupling. The beads were first reacted with MAL-PEG(3k)-SVA (Laysan Bio) in PBS at room temperature for 30 minutes with gentle rotation to introduce sulphydryl-reactive maleimide handles. Cysteine-terminated peptides with mass-encoded barcodes were then reacted in PBS with up to 30% DMF to the PEG-coated magnetic beads overnight at room temperature with gentle rotation. Following overnight incubation, any remaining sulphydryl-reactive handles were quenched with i-cysteine (Sigma Aldrich). Peptide-functionalized magnetic beads were then pooled, washed in bead wash buffer, buffer exchanged into PBS, resuspended into PBS at the original bead concentration, and stored at 4 °C. Initial peptide concentrations were quantified via LC/MS-MS analysis of stock bead solution.

LC/MS-MS barcode quantification

LC/MS-MS was performed by Syneos Health using a Sciex 6500 triple quadrupole mass spectrometer. Samples were treated with ultraviolet irradiation to photobleach the 3-amino-3-(2-nitro-phenyl)propionic acid (ANP) and liberate the barcode from residual peptide fragments. Samples were extracted by solid-phase extraction and analyzed by multiple reaction monitoring by LC/MS-MS to quantify concentrations of each barcoded mass variant. Analyte quantities were normalized to a spiked-in internal standard, and concentrations were calculated from a standard curve using peak area ratio (PAR) to the internal standard.

In vitro recombinant protease cleavage assays

For bead cleavage assays, peptide-functionalized magnetic beads were synthesized and prepared as described above. Recombinant proteases (Enzo Life Sciences, R&D Systems, Haematologic Technologies) were selected on the basis of substrate specificity. Assays were conducted in appropriate enzyme buffer according to manufacturer specifications (Supplementary Table S2). For each cleavage reaction, 1.2 × 10⁶ beads, consisting of an isokinetic mixture of beads carrying unique substrate-barcode pairs and resuspended in 60 μL of appropriate buffer, were added to a PCR tube, and 20 μL of recombinant protease was added to achieve a final enzyme concentration of...
12.5 nmol/L in 80 μL reaction volume. Reactions were incubated at 37°C with gentle rotation for 1 hour. Following incubation and proteolysis, two rounds of magnetic bead pull-down were used to isolate liberated barcodes present in the supernatant. Samples were frozen at −80°C until analysis by LC/MS-MS. Initial peptide concentrations were quantified via LC/MS-MS analysis of stock bead solution. To determine the relative concentrations of cleavage-liberated barcodes, liberated barcode PAR values were normalized to stock PAR values.

For fluorescence cleavage assays, intramolecularly quenched peptide substrates (1 μmol/L) were incubated with recombinant proteases (125 nmol/L for Supplementary Fig. S16; otherwise 12.5 nmol/L) in a reaction volume of 30 μL in MMP buffer at 37°C. Proteolytic cleavage of substrates was quantified by increases in fluorescence over time as measured by fluorimeter (Tecan Infinite M200 Pro).

**Bead cleavage assays with tissue homogenates**

Prior to the cleavage assay, fresh-frozen prostates were placed in tubes with high-impact zirconium beads (Benchmark Scientific), and PBS was added to achieve a concentration of 100–300 mg tissue per mL of PBS. Homogenization was performed using a BeadBeater homogenizer (BioSpec). Bradford assay (Bio-Rad) was performed, and all samples were prepared to twice the desired final assay protein concentration of 1 mg/mL. For inhibited conditions, 1 mmol/L AEBSF (Sigma Aldrich) or 2 mmol/L marimastat (Sigma Aldrich) were preincubated with tissue homogenates for at least 30 minutes prior to cleavage assay.

Magnetic beads functionalyzed with mass-barcoded peptide substrates were synthesized and prepared. For each cleavage reaction, 1.2 × 10^8 beads, comprised of a multiplexed cocktail of beads carrying unique substrate-barcode pairs and resuspended to a concentration of 1 mg/mL. To determine the relative concentrations of cleavage-liberated barcodes, PAR values were normalized to per-sample sum of PARs across all barcodes.

**In situ** zymography with AZPs

Organs were extracted and immediately embedded and frozen in OCT compound (Sakura). Cryosectioning was performed at the Koch Institute Histology Core (Cambridge, MA). Fresh-frozen human organs (2 mg/mL protein concentration) was added to the bead solution to achieve a final peptide concentration of 1 μmol/L in appropriate enzyme buffer at 37°C for at least 2 hours to run cleavage reactions to completion. Details of AZP-protease pairs are provided in Supplementary Table S3. Following precleavage with recombinant enzymes, AZP solutions were diluted to a final peptide concentration of 1 μmol/L in appropriate buffer. Cognate intact AZPs (1 μmol/L) and precleaved AZPs were applied to fresh-frozen sections of normal mouse colon (slide preparation described above) and incubated at 37°C for 30 minutes. The MMP12-responsive probes incorporating the substrate S16, S16-Z and S16-QZ, were additionally characterized using precleavage by MMP12, followed by application to fresh-frozen sections of normal mouse colon and incubation at 4°C for 30 minutes. Following AZP incubation, slides were washed, stained with Hoechst, mounted, and scanned.

**ELISA for MMP12**

Tissue levels of MMP12 in Hi-Myc and healthy FVB/NJ prostate homogenates were measured by ELISA according to manufacturer’s protocol (ab246540, Abcam). Prostate homogenates were prepared as described above. Protein concentration was measured via Bradford assay (Bio-Rad) and normalized across samples.

**Immunofluorescence staining for uPA and MMP12**

Slides of fresh-frozen tissue sections were prepared as described above. Slides were blocked in serum-based blocking buffer and incubated with primary antibody against uPA (MAB9185, R&D, Systems, 25 μg/mL) or MMP12 (MA5–32011, Invitrogen, 20 μg/mL). Slides were washed in PBS, incubated with the appropriate secondary antibody (Invitrogen) and Hoechst, and washed in PBS. Slides were mounted and scanned as described previously.

**Quantification of AZP and immunofluorescence staining**

AZP and immunofluorescence staining was quantified in QuPath 0.2.0-m9 (32). To perform cell-by-cell analysis, segmentation was performed via watershed cell detection on the DAPI (nuclear) channel. Binary classification was performed to identify cells that were positive or negative for E-cadherin, S16-Z, and Ki-67. E-cadherin–positive cells had maximum cytoplasmic E-cadherin intensity of greater than or equal to 65 AU. S16-Z–positive cells had mean nuclear S16-Z intensity of greater than or equal to 20 AU. Ki-67–positive cells had mean nuclear Ki-67 intensity of greater than or equal to 10 AU. All cells that were not positive for a particular marker were considered negative for that marker. Classification maps were generated using the object classification function in QuPath. Density plots were generated using the descatter function in MATLAB R2017b. Additional statistical analyses were conducted in GraphPad 8.0 (Prism).

To quantify relative binding of precleaved and intact AZPs, mean nuclear AZP intensity was averaged across the entire TMA core. Nuclei with a polyR intensity of less than 3 were excluded from analysis.
AZP PEGylation
The peptides S16-QZ and dS16-QZ were reconstituted to 1 mg/mL in water, then reacted with mPEG-Maleimide, MW 2000 g/mol (Laysan Bio), for PEG coupling via maleimide-thiol chemistry. After completion of the reaction, the final compounds were purified using HPLC. All reactions were monitored using HPLC connected with mass spectrometry. Characterization of final compounds, S16-QZ (PEG2K) and dS16-QZ (PEG2K), using HPLC and MALDI-MS indicated that products were obtained with more than 90% purity and at the expected molecular weight.

In vivo studies in Hi-Myc model
Male Hi-Myc mice (FVB-TgARR2/Pbsn-MYC7Key/Nci; 32–36 weeks) and age-matched FVB/N healthy controls (Jackson Labs; 28–36 weeks) were anesthetized using isoflurane inhalation (Zoetis). S16-QZ (PEG2K) or dS16-QZ (PEG2K) (4.5 nmol in 0.9% NaCl) was administered intravenously via tail vein injection. Four hours after probe injection, mice were euthanized by isoflurane overdose followed by cervical dislocation, and prostates were dissected as described previously. Explanted prostates were imaged on an in vivo imaging system (IVIS, PerkinElmer) by exciting Cy5 at 640 nm and measuring emission at 680 nm. Fluorescence signal intensity was quantified using the Living Image software (PerkinElmer).

Statistical analysis
Principal component analysis was performed in the R statistical environment (https://www.r-project.org/) using the prcomp function. Hierarchical clustering was performed using GENE-E (Broad Institute; https://software.broadinstitute.org/GENE-E/). All remaining statistical analyses were conducted in GraphPad Prism 8.0. Sample sizes, statistical tests, and p-values are specified in figure legends.

Data availability
The data that support the findings of this study are available upon request to sbhatia@mit.edu. There is no data deposition relevant to the results of this study.

Results
In situ labeling of protease activity with AZPs
We first sought to develop and validate a modular, cleavage-based zymography assay to localize protease activity within its native biological context. In situ labeling of protease activity offers several capabilities, including the opportunity to elucidate the spatial distribution of protease activity within a tissue and to colocalize protease activity with histological markers (Supplementary Table S4). Drawing from previous work using cell-penetrating peptides (18, 19, 33), we hypothesized that peptides that consist of a cationic poly-arginine (polyR) domain complexed to an anionic poly-glutamic acid (polyE) domain via a protease-cleavable linker could enable in situ labeling of protease activity on fresh-frozen tissue sections (Fig. 1A). Although cell-penetrating peptides had previously been applied ex vivo to fresh, live tissue specimens (33), in which active uptake mechanisms such as endocytosis remain intact, it remained unknown whether peptides of this design could achieve protease-dependent tissue binding on frozen sections, where these uptake mechanisms are no longer active. Thus, we hypothesized that, upon application to fresh-frozen tissue sections, degradation of the protease-cleavable linker component of these AZPs by tissue-resident enzymes would liberate the fluorophore-labeled polyR, which could then electrostatically interact with negatively charged molecules in the tissue, enabling localization by microscopy.

We first tested this technique on a tissue type with a known spatial distribution of protease expression. Because colon epithelial cells secrete serine proteases (34) including urokinase plasminogen activator (uPA; Supplementary Fig. S1; ref. 35), we synthesized a Cy5-labeled AZP, termed S6-Z (Supplementary Table S1), containing a substrate expected to be cleaved by serine proteases (36), and applied it to fresh-frozen sections of normal mouse colon (Fig. 1B). Fluorescence signal from S6-Z was detected in the epithelial regions of the colon, and a free polyR was used as a binding control (Fig. 1C). We synthesized a noncleavable, d-stereoisomer version, termed dS6-Z, to assess whether proteolytic processing was required to activate the probe, and observed no signal following application of dS6-Z to fresh-frozen colon tissue, indicating that proteolytic cleavage was necessary for tissue binding (Fig. 1C). Furthermore, this spatially resolved S6-Z labeling was abrogated by addition of the serine protease inhibitor 4-(2-aminoethyl)benzenesulfonyl fluoride hydrochloride (AEBSF; Fig. 1C).

To characterize the extent and specificity of this activity-dependent probe localization, we applied S6-Z to colon sections and confirmed for the epithelial cell marker E-cadherin. As the primary source of serine proteases in this tissue has been shown to be colon epithelial cells (Supplementary Fig. S1; refs. 34, 35), our observation that E-cadherin–positive cells exhibited increased labeling by S6-Z than E-cadherin–negative cells (P < 1 × 10−15) was consistent with our hypothesis that AZPs enable localization of cell type–specific protease activity in situ (Fig. 1D and E). Furthermore, a quenched version of this AZP, wherein proteolytic cleavage is required for fluorescence activation, labeled serine protease activity in colon epithelium with reduced background signal (Supplementary Fig. S2A–S2C). Together, these results indicate that AZPs can directly measure peptide cleavage events in situ to spatially localize protease activity with low background binding.

Discovery of human prostate cancer-responsive protease substrates
We next set out to validate AZPs as a tool to measure enzyme activity in human tumor tissues and to thus identify peptide substrates relevant to designing conditional diagnostics and therapeutics for human cancer. To this end, we designed a library of 19 AZPs based on a panel of peptides previously found by our group to be recognized by proteases dysregulated in human prostate cancer (Supplementary Table S1; ref. 36). With the exception of the protease-cleavable linker and fluorophore, these AZPs were identical in design to the serine protease-responsive S6-Z. We first sought to verify that proteolysis was required for tissue binding of probes across the entire AZP library. We found that AZP precleavage by a cognate recombinant protease with specificity for the AZP linker (Supplementary Table S3) resulted in increased tissue binding for all 19 probes (Supplementary Fig. S3). The proteolysis–dependent tissue labeling observed across the probe library supports the modularity of the AZP platform.

Given that serine proteases are among those known to be dysregulated in human prostate cancer (36), we selected two serine protease-responsive AZPs (S10-Z and S2-Z) to evaluate against a fresh-frozen TMA containing biopsies from normal prostates and prostate cancer tumors across a range of Gleason scores (Supplementary Fig. S4A–S4D). Tissue binding of S10-Z (Fig. 2A) and S2-Z (Supplementary Fig. S5A) appeared elevated in prostate cancer tissue relative to normal prostate (S10-Z, Fig. 2B; S2-Z, Supplementary Fig. S5B). Quantitative analysis indicated that binding across the TMA for both AZPs was significantly abrogated by a broad-spectrum cocktail of protease inhibitors (S10-Z, Fig. 2C; S2-Z, Supplementary Fig. S5C). Both

Soleimany et al.
S10-Z (P = 0.0063, Fig. 2D) and S2-Z (P = 0.0284, Supplementary Fig. S5D) exhibited significantly increased labeling of prostate cancer relative to normal prostate tissue, with nearly all tumors demonstrating enhanced probe binding relative to controls [area under the curve (AUC) by receiver-operating characteristic (ROC); S10-Z AUC = 0.948, Fig. 2E; S2-Z AUC = 0.917, Supplementary Fig. S5E]. Increased labeling of both probes was distributed across prostate cancer tumors of all Gleason scores (Supplementary Fig. S6A and S6B), suggesting that conditional diagnostics or therapeutics incorporating these linkers could be broadly applied across a heterogeneous population of patients with prostate cancer. These findings demonstrate that serine protease activity is dysregulated in human prostate cancer, establish the compatibility of AZPs with clinically available biospecimens such as biopsy cores, and suggest that AZPs may be used to identify peptide substrates that are preferentially cleaved by proteases in human cancer.

Identification of a prostate cancer-responsive peptide substrate in the Hi-Myc model

We next aimed to incorporate our in situ activity probes into a generalizable pipeline to rationally design a protease-activatable...
diagnostic from the bottom up. We therefore turned to the Hi-Myc GEMM, wherein c-Myc is overexpressed in the murine prostate, resulting in invasive prostate cancer (31). We first set out to query the landscape of proteolytic activity in Hi-Myc prostates through multiplexed substrate screening. To this end, we developed a method to measure cleavage of a multiplexed substrate panel in a single-reaction volume. We selected a panel of 18 peptides previously found by our group to be recognized and cleaved by proteases that are dysregulated in prostate cancer (36), and appended each peptide with a unique barcode (7) consisting of the 14-mer glutamate-dyning peptide-functionalized bead cocktail with each of 10 recombinant proteases to assay their individual cleavage patterns and kinetics. Unsupervised hierarchical clustering of the cleavage data revealed distinct substrate specificities of the screened metallo- and serine proteases (Supplementary Fig. S7A). Furthermore, we found that the cleavage scores measured through the multiplexed bead screen generally correlated with those from a screen of quenched fluorescent versions of the same substrates incubated individually with the same selected recombinant proteases (Supplementary Fig. S7B and S7C; ref. 36). Cleavage kinetics were assessed by performing magnetic separation at multiple time intervals following addition of protease controls against our peptide-functionalized bead library and found intrinsic protease activity dysregulation in the Hi-Myc GEMM. We screened homogenates of prostates from Hi-Myc mice and age-matched healthy controls against our peptide-functionalized bead library and found distinct cleavage patterns between diseased and healthy prostates (Fig. 3A). Barcode concentrations are then measured by mass spectrometry (Supplementary Fig. S7), we predicted that the selected recombinant proteases (Supplementary Fig. S7), we predicted that the multiplexed bead assay can be used to faithfully query cleavage specificity of substrate cleavage.

To validate that this assay could capture protease-substrate specificities, we incubated the peptide-functionalized bead cocktail with each of 10 recombinant proteases to assay their individual cleavage patterns and kinetics. Unsupervised hierarchical clustering of the cleavage data revealed distinct substrate specificities of the screened metallo- and serine proteases (Supplementary Fig. S7A). Furthermore, we found that the cleavage scores measured through the multiplexed bead screen generally correlated with those from a screen of quenched fluorescent versions of the same substrates incubated individually with the same selected recombinant proteases (Supplementary Fig. S7B and S7C; ref. 36). Cleavage kinetics were assessed by performing magnetic separation at multiple time intervals following addition of protease controls against our peptide-functionalized bead library and found distinct cleavage patterns between diseased and healthy prostates (Fig. 3A). Barcode concentrations are then measured by mass spectrometry (Supplementary Fig. S7), we predicted that the multiplexed bead assay can be used to faithfully query cleavage specificity of substrate cleavage.

We then assessed whether the multiplexed bead assay could be used to identify tumor-specific peptide substrates and patterns of protease activity dysregulation in the Hi-Myc GEMM. We screened homogenates of prostates from Hi-Myc mice and age-matched healthy controls against our peptide-functionalized bead library and found distinct cleavage patterns between diseased and healthy prostates (Supplementary Fig. S7A). Intriguingly, this assay revealed that a single-peptide sequence (“S16,” or “S16-M” when coupled to mass barcode; Supplementary Table S1) was differentially cleaved by Hi-Myc prostate homogenates relative to samples from healthy control mice (Fig. 3B). On the basis of the results of the bead screen against recombinant proteases (Supplementary Fig. S7), we predicted that the observed cleavage of the S16-M probe was likely mediated by MMP activity. Consistent with this hypothesis, we found that pretreatment of the prostate homogenates with the MMP inhibitor marimastat (MAR)
Figure 3.
S16 is preferentially cleaved by metalloproteinases in the Hi-Myc model. **A**, Multiplexed protease activity profiling with barcoded substrate libraries. Uniquely barcoded protease-cleavable peptide substrates are coupled to magnetic beads. Multiplexed bead complexes are incubated with recombinant enzymes or biospecimens. Substrate liberation liberates barcodes, which can be isolated via magnetic pull-down of beads and quantified to measure substrate cleavage. **B**, Volcano plot showing log2-fold change in cleavage product concentrations between Hi-Myc (n = 7) and healthy (n = 5) prostate homogenates (x-axis) and −log10(P_adj) (y-axis). Each point represents one substrate. Significance was calculated by two-tailed t test, followed by adjustment for multiple hypotheses using the Holm–Sidak method. Dotted line is at P_adj = 0.05. **C**, Quantification of S16-M cleavage, measured as the fraction of total peak area ratio (PAR) signal from all screened peptides, for healthy prostate homogenates (n = 5) and Hi-Myc prostate homogenates, either uninhibited (Hi-Myc, n = 7), or in the presence of the MMP inhibitor marimastat (Hi-Myc + MAR, n = 4) or the serine protease inhibitor AEBSF (Hi-Myc + AEBSF, n = 4; mean ± SD; one-way ANOVA with Tukey correction for multiple comparisons; ***P < 0.0001; ns = not significant**).
In MMP12 in Hi-Myc prostates relative to age-matched healthy controls (P = 0.0034, Supplementary Fig. S15D). In addition, Hi-Myc prostates stained positively for MMP12, whereas healthy prostates did not (Supplementary Fig. S15E). MMP12 was also found to localize broadly throughout the histologically normal, S16-Z, Ki-67–positive glands of Hi-Myc tissue (Fig. 4F). Overall, these results suggest that MMP12 may be responsible for S16 cleavage in Hi-Myc prostates, highlighting the power of AZPs to enable in situ localization and biological characterization of protease dysregulation in cancer.

In vivo validation of a protease-activated probe in the Hi-Myc model

Having leveraged multiplexed screening and AZP profiling to identify and localize S16 cleavage in Hi-Myc prostates, we sought to design an in vivo probe that could be specifically activated within

Figure 4.
S16 cleavage localizes to established tumors and proliferative, MMP12-positive glands in the Hi-Myc model. A, The MMP-responsive AZP S16-Z was applied to Hi-Myc prostate tissue sections. Hematoxylin and eosin staining of Hi-Myc prostate tissue; representative example is shown. Solid and dashed boxes indicate tissue regions in B and C, respectively. Scale bar, 500 μm. B, Staining of boxed Hi-Myc tumor region from A with S16-Z (left). A consecutive section was stained with S16-Z in the presence of the MMP inhibitor marimastat (S16-Z + MAR, right). Scale bar, 50 μm. C, Application of S16-Z (green), with or without MAR, to prostate tissues from Hi-Myc and healthy mice with costaining for the proliferation marker Ki-67 (red). Sections were counterstained with DAPI (blue). Detected cells were classified on the basis of S16-Z and Ki-67 staining intensities to produce cell classification maps (red, Ki-67+; green, S16-Z+; yellow, S16-Z+ and Ki-67+, ++). Images of Hi-Myc tissues show the glandular region boxed in A. Scale bars, 200 μm. D, Quantification of fraction of detected nuclei positive for S16-Z in healthy, MMP-inhibited healthy (Healthy + MAR), Hi-Myc, and MMP-inhibited Hi-Myc (Hi-Myc + MAR) prostate tissue sections (n = 2 consecutive sections/group, >100,000 cells per section; mean ± SD; two-tailed unpaired t test; *, P = 0.00794; **, P = 0.000803). E, Quantification of fraction of detected nuclei positive for both S16-Z and Ki-67 (n = 2 consecutive sections/group, >100,000 cells per section; mean ± SD; two-tailed unpaired t test; *, P = 0.0185; ***, P = 0.000429). F, Immunofluorescence staining for MMP12 (yellow) in glandular region (A) of Hi-Myc prostate tissue. Sections were counterstained with DAPI (blue). Scale bar, 200 μm.
In Situ Localization of Protease Dysregulation in Cancer

**Figure 5.** An activatable imaging probe incorporating S16 enables classification of prostate cancer in vivo. **A,** The quenched probe S16-QZ, consisting of a fluorophore-tagged polyR (gray star + blue rectangle) and quencher-tagged polyE (orange hexagon + red rectangle) linked via an MMP-cleavable linker (green), was incubated with recombinant MMP12, and fluorescence activation was monitored over time (left). Dequenching measurements for S16-QZ and d-stereoisomer dS16-QZ following incubation with recombinant MMP12 (right; n = 3 replicates/condition; mean ± SD). **B,** Binding of intact or MMP12 precleaved (PC) S16-QZ to fresh-frozen sections of healthy mouse colon tissue following incubation at 4°C. Scale bars, 25 μm. **C,** Quantification of S16-QZ binding for intact probe or probe precleaved by MMP12 (n = 2 replicates; mean ± SD; two-tailed unpaired t-test, \( P < 0.0382 \)). **D,** S16-QZ-(PEG2K) or uncleavable dS16-QZ-(PEG2K) was administered intravenously into age-matched Hi-Myc and healthy mice. Four hours after injection, prostates were excised and imaged by IVIS (n = 5/group). Images of representative prostates are shown at right. **E,** Quantification of epifluorescence radiant efficiency from experiment in D via IVIS imaging (n = 5/group; mean ± SD; one-way ANOVA with Tukey correction for multiple comparisons; \(* * * *, P < 0.0001; \text{ns}, P = 0.0990\)). **F,** ROC curve showing performance of S16-QZ-(PEG2K) signal in discriminating healthy from Hi-Myc prostate explants (AUC = 1.000, 95% confidence interval 1.000–1.000; P = 0.0090 from random classifier shown in dashed line).

Having verified that proteolytic processing was required for both fluorescence activation and tissue binding of this prostate cancer-targeted probe, we next sought to assess whether this probe could enable detection of disease after systemic in vivo administration. S16-QZ and the uncleavable control peptide, dS16-QZ, were PEGylated to improve solubility, increase circulation time, and drive tissue accumulation (33). Importantly, following PEGylation, the cleavable probe remained responsive to MMP12 in vitro (Supplementary Fig. S16). PEGylated S16-QZ and dS16-QZ were subsequently administered intravenously into Hi-Myc mice and age-matched healthy controls (Fig. S5D). Mice were assessed at 32–36 weeks of age, at which point, adenocarcinoma is typically present in Hi-Myc prostates (31). Significantly increased Cy5 fluorescence was observed in explanted prostates of Hi-Myc mice injected with S16-QZ relative to the uncleavable dS16-QZ (P < 0.0001, Fig. 5E), whereas no such difference between the probes was observed in healthy prostates (P = 0.0990, Fig. 5E). Furthermore, Cy5 fluorescence after S16-QZ injection was found to be significantly increased in Hi-Myc prostates relative to healthy prostates (P < 0.0001, Fig. 5E), enabling perfect discrimination of Hi-Myc and healthy mice (AUC = 1.000, Fig. 5F). These results demonstrate that peptide substrates nominated via ex vivo activity profiling in tumor specimens can be directly incorporated into conditionally activated agents for in vivo tumor targeting and detection.

**Discussion**

In this work, we developed a modular assay to localize protease activity in situ and incorporated this method into a generalizable pipeline to rationally design protease-activated diagnostics and therapeutics. By applying our localization probes, AZPs, to a human prostate cancer tumor microarray, we identified two peptides that are preferentially cleaved by human prostate cancer-associated proteases, thereby supporting the ability of AZPs to directly validate candidate cleavable linkers in patient-derived tissue samples. Next, we demonstrated a bottom-up...
approach to the development of activatable diagnostics in the Hi-Myc prostate cancer GEMM. We identified a peptide, S16, cleaved specifically by prostate cancer-associated metalloproteinases, and found, using AZPs, that its cleavage localized broadly throughout tumors and proliferative, MMP12-positive glands in diseased prostates. Finally, we demonstrated that this disease-responsive substrate characterized via ex vivo activity profiling could be integrated into a protease-activated diagnostic for in vivo use.

Integrating multiplexed screens with cleavage-based in situ zymography assays presents a new framework relevant to both discovery and engineering efforts that seek to understand and leverage protease dysregulation in cancer (Fig. 6A–C). Each of these methods provides distinct advantages and complementary information. Multiplexed screening with physiochemically diverse, combinatorial peptide libraries, generated via display-based (39, 40) or synthetic (26, 41) strategies, could provide a search space of sufficient size and diversity to enable nomination of disease-specific substrates without any prior knowledge of enzyme targets. Subsequent substrate motif and inhibitor ablation analysis could be used to identify protease classes contributing to substrate cleavage. Although bulk screens can identify lead candidates from multiplexed panels, in situ labeling is necessary to explore underlying biology and to validate the relevance of these substrates for specific applications. For example, an activatable therapeutic like a probody would ideally incorporate a peptide substrate that is cleaved broadly throughout the tumor, whereas an activatable imaging probe designed to monitor responses to immunotherapy might leverage a peptide that is strictly cleaved by proteases produced by tumor-infiltrating lymphocytes.

Here, we demonstrate the power of this approach in the Hi-Myc model of prostate cancer, identifying the disease-responsive peptide substrate S16 from a multiplexed screen and using in situ activity profiling with AZPs, coupled with immunostaining and quantitative analysis, to find that S16 cleavage localized to both tumor cells and Ki-67–positive glands that had not yet progressed to adenocarcinoma. This ability to quantitatively colocalize protease activity signals with other markers may enable concurrent identification of both disease-specific peptide linkers and biological targets for rational design of protease-activated diagnostics and therapeutics. Together with our in vivo validation of an imaging probe incorporating S16, the observation that AZPs localized S16 cleavage in premalignant prostatic glands suggests that, if incorporated into a diagnostic or therapeutic, this substrate could enable detection or interception of early-stage disease in the Hi-Myc model.

AZPs offer several advantages over existing methods of measuring and localizing protease activity in situ. Although in situ activity profiling with fluorescently tagged probodies has recently been shown to correlate with in vivo therapeutic efficacy, this approach requires target antigen expression for probe binding and is therefore limited in its generalizability (29). AZPs address this limitation in that they provide a modular, antigen-independent means to directly measure substrate-specific protease activity. Activity-based probes, which covalently bind to protease active sites, consist of two components (a recognition sequence and a reactive functional group) that must be redesigned for each new protease target (5). AZPs, in contrast, consist of two constant regions (polyR and polyE) and a single protease-cleavable linker that can be replaced with any sequence of interest (Fig. 1A). This modularity enabled us to synthesize a library of 19 AZPs (Supplementary Table S1), all of which were dependent on proteolysis for tissue labeling (Supplementary Fig. S3). Therefore, we expect that AZPs could readily be designed to incorporate any candidate peptide substrate, a degree of modularity unmatched by existing in situ probes.

This work also establishes AZPs as a molecular tool to probe protease-mediated biological processes in situ and to thereby functionally dissect the crucial roles of proteases in cancer development and progression. Because proteases exert their function through their activity (2, 5), direct measurements of protease activity rather than abundance may enable new insights into the roles of enzymatic biology in cancer. In this work, we uncovered an increase in metalloproteinase activity in established prostate tumors and, unexpectedly, in histologically normal prostatic glands in the Hi-Myc model. This finding was powered by the identification of S16, a metalloproteinase-sensitive peptide cleaved by proteases in the Hi-Myc model, followed by in situ labeling with S16-Z. Additional investigation revealed that S16-Z–positive, histologically normal glands, in addition to established tumors, were also positive for the proliferation marker Ki-67 and overexpressed MMP12. Because these cells exhibited two features of cancer, dysregulated cell division and aberrant protease activity, our
observations raise the possibility that these glands may be pre-malignant. MMP12 has previously been shown to inhibit tumor growth in mice (42), an effect that appears to derive from its ability to cleave plasminogen and generate angiostatin, a potent angiogenesis antagonist (43). Although mechanistic experiments will be necessary to fully elucidate the role of MMP12 in the pathogenesis of prostate cancer, the intensity of S16-Z staining of Ki-67 in situ division in this disease model. As demonstrated by these data, integrating in situ protease activity profiling, immunostaining, and quantitative image analysis could provide a powerful paradigm to dissect enzymatic biology in cancer initiation, progression, and spread.

Although the cleavage-based AZPs presented here offer several advantages over existing probes, their primary limitation is specificity, as proteases of the same class exhibit substantial cross-cutting against short peptides. Multiplexed screens and in situ labeling with AZPs can be readily deployed as tools to nominate and validate peptide linkers for conditionally activated diagnostics or therapeutics, which must be selective for cancer relative to healthy tissue but need not be specific to any one protease (11). In contrast, further optimization is needed before such cleavage-based methods can be reliably leveraged as a tool to dissect protease biology with single-enzyme specificity. To globally profile proteolytic cleavage without bias, it will be critical to scale multiplexed screens beyond rationally selected substrate panels. To this end, high-throughput screens of large, diverse libraries of phage-displayed substrates (40) or peptides enriched with unnatural amino acids (41, 44) could identify cleavage sites for a broad range of proteases and yield protease substrates with dramatically improved specificities. Finally, AZPs may also have utility in precision medicine applications, in which AZPs could be applied to individual patient biopsy samples to identify peptide linkers with maximal on-target cleavage. However, prior to clinical adoption, it will be necessary to establish reference ranges for individual AZPs by testing across multiple tissue samples with known levels of protease activity. In summary, we have engineered a new, highly modular class of in situ activity probes, AZPs, to identify tumor-specific peptide substrates and to localize their cleavage in tissue sections. We integrated multiplexed substrate screening with AZP profiling to achieve the bottom-up design of an activatable imaging probe in a prostate cancer GEMM and also showed that AZPs can be used to directly probe protease activity in human biopsy specimens. We expect that AZPs, which can be readily adapted to any tumor type or set of peptide substrates, will help elucidate the multifaceted roles of proteases in tumor biology and accelerate the development of next-generation agents that leverage protease activity to detect and target cancer.
